

Flare-Induced Interaction Lengths in Supersonic, Turbulent Boundary Layers

A. Roshko* and G. J. Thomke†

Douglas Aircraft Company, El Segundo, Calif.

Experimental results are presented for the effects of Mach number, Reynolds number, and corner angle on flare-induced separation of a supersonic, turbulent boundary layer. Measurements were obtained for upstream interaction distance l_0 from the flare to the beginning of the interaction for Mach numbers $2 \leq M \leq 4.5$, boundary-layer thickness Reynolds numbers $10^5 < R_\delta < 10^6$, and adiabatic wall conditions. Flares of angle $9^\circ \leq \alpha \leq 40^\circ$ were attached to a hollow-cylinder model of 12 in. diam at either $x_c = 14$ or 28 in. downstream from the sharp leading edge. It was found that l_0/δ_0 decreases with increasing Mach number and Reynolds number and increases with flare angle. For constant α , when l_0/δ_0 is plotted vs the local skin-friction coefficient, C_{f0} , the Mach number dependence disappears. From this observation, a simple correlation formula was obtained and used to compare results from other investigations, and also to correlate incipient separation data.

Nomenclature

C_f	$= 2\tau_w/\rho_e U_e^2$, local skin-friction coefficient
l	$=$ interaction length, measured upstream from corner
M	$=$ Mach number
P	$=$ pressure
r	$=$ radius of cylinder outer surface
R_Δ	$= \rho_e U_e \Delta / \mu_e$, Reynolds number based on $\Delta = \delta, \delta^*, \theta$, or $c = x_c$
T	$=$ temperature
U	$=$ velocity
x	$=$ distance downstream from leading edge of cylinder
y	$=$ radial distance from cylinder surface
α	$=$ flare angle, deg
δ	$=$ boundary-layer thickness
δ^*	$=$ boundary-layer displacement thickness
θ	$=$ boundary-layer momentum thickness
ξ	$=$ wetted distance from compression corner, positive upstream
ρ	$=$ density
σ	$=$ upstream influence coefficient

Subscripts

c	$=$ undisturbed conditions at compression corner
e	$=$ freestream conditions
i	$=$ conditions for incipient separation
o	$=$ undisturbed conditions at beginning of interaction
P	$=$ plateau
r	$=$ recovery conditions
s	$=$ conditions at separation point
t	$=$ freestream total conditions
w	$=$ conditions at the surface

Introduction

THE investigations reported in this paper are a natural development from the earlier work of the

authors¹ on incipient separation at very high Reynolds number which showed trends quite different from those which could be extrapolated from prior results at lower values of Reynolds number. Specifically, in the range $10^8 \leq R_c \leq 10^9$, the ramp angle needed to induce separation α_i increased with R_c . This is opposite to what had been observed at values of R_c below 10^7 by Kuehn² and others. However, Settles and Bogdonoff³ found that the angle for incipient separation α_i does not vary with R_c , while Law⁴ found that it increases; the latter results tend to confirm the trends of Ref. 1.

It was natural to ask whether the increased "resistance to separation" at high Reynolds number occurs also for values of $\alpha > \alpha_i$, i.e., for separated flow. Indeed, the few results obtained¹ indicated that the interaction lengths l_0 and l_s (which characterize the beginning of the pressure rise and the location of the separation point, respectively, upstream of the ramp), normalized by the boundary-layer thickness (δ_0) just ahead of the interaction, decreased with increasing R_c . Other evidence for the decrease of l_0/δ_0 and l_s/δ_0 with increasing R_c was also available from the experimental investigations of Refs. 3 and 4 as well as the theoretical results of Refs. 5-7.

It is curious that up to now there has been no cogent account of interaction length behavior in supersonic, turbulent boundary layers. The problem has attracted the attention of many investigators, and various correlations have been attempted, but with little success. A difficulty has been the lack of experimental data for conditions varied systematically over a sufficiently broad range. In a survey of over 100 papers and reports giving experimental results, we found it problematic to sort out trends. The great bulk of the data were in a range of Reynolds number R_c from about 10^5 to 10^7 , or even narrower—this dictated by the characteristics of the typical small or medium-sized supersonic wind tunnels in which research of this kind was ordinarily conducted. In this range, the flows were transitional more often than not, or had hardly recovered from the effects of transition or tripping, so that the establishment of accurate trends for purely laminar or purely turbulent separation proved difficult. The situation was compounded by the facts that any one investigation was usually conducted over a rather limited range (if any) of Mach number and Reynolds number, and different investigators used different ramp angles, usually with little variation. It was therefore difficult, even with interpolation and extrapolation, to put together a broad picture.

In designing the experiments described here, the aim was to take advantage of the model size and high Reynolds number capability offered by a large wind tunnel so that l_0/δ_0 or l_0/x_c could be varied systematically over as wide a range as

possible of the relevant parameters, viz., the ramp angle (α), Mach number (M_e), and Reynolds number (R_e or R_δ). It would have been desirable to continue with the experimental arrangement of Ref. 1, where wall boundary-layer thicknesses ranged from 3-6 in., but model blockage and shock-wave induced interference effects would have appreciably diminished the range of α and ℓ_0/δ_0 for which valid data could be obtained. Further study indicated that the desired goals could best be achieved by using a 1-ft-diam hollow cylinder to which flares of various angles could be attached. Experimental conditions would cover the Reynolds number range $10^6 \leq R_\delta \leq 10^7$ —i.e., one decade lower than that of Ref. 1. With a sharp leading edge, supersonic flow through the inlet, and boundary-layer thicknesses small compared to the cylinder radius ($\delta/r < 0.07$), the boundary layer and adjacent flowfield would be similar to those for a flat plate. However, for large separation regions ahead of the larger flares, an effect of the axisymmetric parameter x_c/r could be expected.

Experimental Arrangement and Procedure

Wind Tunnel

The experiments were made in the 4×4-ft Trisonic Wind Tunnel (blowdown) located at the McDonnell Douglas Aerophysics Laboratory in El Segundo, Calif. Test-section Mach number was varied from 2.0-4.5; unit Reynolds number was varied from 0.5-2 million/in. by adjusting total pressure. Depending upon Mach number, total temperatures were in the range from 520-630° R and provided nearly adiabatic wall conditions for the model. During a run, total temperature decreased slightly (no more than 10° over the total run interval, and less than 5° during a data measurement interval).

Model and Instrumentation

The basic part of the model, the hollow cylinder, was a steel tube with 11.94 in. o.d. and a wall thickness of 0.34 in. The outer surface of the tube was machined and polished to a 32- μ in. finish. The inlet section was chamfered internally at an angle of 4° and honed to provide a sharp leading edge. Compression corners were formed on the outer surface of the cylinder by attaching to it two flare halves, separated by splitter plates, as shown in Fig. 1. The feasibility of using splitter plates had been studied in some previous, unpublished work (related to that in Ref. 8) on an axisymmetric, downstream-facing step, where it was found that the presence of splitter plates in the base region had no effect on the pressure distribution or the extent of the separated region, even when the circumferential distance between the plates was as small as 45° (compared to 180° in the present case).

Fig. 1 Model with 40°/30° half-flares at $x_c = 28$ in.

Flares were made of aluminum and paired according to the following values for α : 9-13, 19-20, 22-25, 25-25 (with and without splitter plates), 27-35, and 30-40°. Slant lengths ranged from 4.6 in. ($\alpha=9^\circ$)-5.9 in. ($\alpha=40^\circ$). Flare pairs could be positioned at two locations on the cylinder, $x_c = 14$ or 28 in. measured downstream from the leading edge of the cylinder to the leading edge of each flare. Corresponding values of the axisymmetric parameter x_c/r are 2.33 and 4.66, respectively.

The cylinder surface was instrumented with 146 orifices (0.03-in. diam) for sensing surface pressure, and a thermocouple for sensing surface temperature. Flares of angle $\alpha \leq 25^\circ$ were instrumented with 16 orifices. Pressures and temperatures were measured with conventional wind-tunnel instrumentation. Schlieren photographs were taken periodically during each run to assist in evaluation of test results, and a traversing probe was used to obtain boundary-layer pitot-pressure profiles.

Procedure

The flare experiments were run at nominal Mach numbers of 2, 2.5, 3, 3.3, 3.5, 3.7, 4, and 4.5, and at tunnel unit Reynolds number of 0.5, 1.0, 1.5, and 2.0 million/in. Thus, by varying both x_c and unit Reynolds number, an eightfold change in R_e was possible. Wall-temperature to recovery-temperature ratios for the model were in the range $0.95 \leq T_w/T_r \leq 1.05$. Mach number, Reynolds number, and flare angle were held constant during a run.

The model was supported in the center of the tunnel as shown in Fig. 1. Various checks showed that the model was aligned parallel to the tunnel flow. Data repeatability was excellent. Splitter plate effects were evaluated at $M=2.5$ ($\ell_0/\delta_0=4$) and $M=3$ by comparing results obtained at $x_c=28$ in. for the $\alpha=25-25^\circ$ pair with and without plates. For each case, plate effects could not be detected.

Pitot-pressure profiles for the undisturbed boundary layer on the cylinder (without flares) were obtained at $x=14$ and 28 in. for the ranges of M and R_e covered in this study. At these locations, representative values of the boundary-layer thickness were $\delta=0.195$ and 0.355 in. Boundary-layer trip devices were not employed. According to data presented by Pate and Schueler⁹, the position of natural transition on the cylinder was estimated to be from 2-8 in. from the leading edge, depending on M and R_e .

Results

The experimental results consisted principally of determinations of the various parameters describing the undisturbed boundary layer on the cylinder, Schlieren photographs of the interaction region, and surface-pressure distributions.

Boundary-Layer Parameters

Boundary-layer Mach number profiles were computed from the measured pitot-pressure values with wall pressure assumed to be constant through the layer. Velocity and density profiles were calculated assuming the temperature profile to be given by

$$T/T_e = (T_w/T_e) + [(T_r/T_e) - (T_w/T_e)](U/U_e) - [(T_r/T_e) - 1](U/U_e)^2 \quad (1)$$

The outer portion of the velocity profile was assumed to be represented by a $1/n$ -type power law, and n was taken to be equal to the slope of the best straight-line fit to logarithmic values of y and U/U_e for $y > 0.03$ in. Values for n ranged from 5.5-6.5 at $x_c=14$ in. and 6.0-7.5 at $x_c=28$ in.

Fig. 2 Boundary-layer thickness at $x_c = 14$ and 28 in.

Fig. 3 Momentum-thickness at $x_c = 14$ and 28 in.

The value of y at $U/U_c = 0.995$ was chosen for δ . The curves of Fig. 2 represent the smoothed values of δ obtained for the undisturbed boundary layer at $x = 14$ and 28 in. for the range of Mach number and (unit) Reynolds number shown. Data scatter about each curve is less than 3%. These results indicate that *dependence of δ on Mach number is small and decreases with increasing Reynolds number.*

The momentum-deficit thickness was determined by graphically integrating the expression

$$\theta = \int_0^\infty (\rho U / \rho_c U_c) [1 - (U/U_c)] dy$$

Values obtained for θ_c are plotted in Fig. 3. To scale the thickness parameters to values of x other than $x = 14$ and 28 in., use was made of the following equations:[†]

$$\delta/x = 0.1215 R_x^{-1/8} \quad (2)$$

$$\theta/x = 0.0125 e^{-M/5} R_x^{-1/8} \quad (3)$$

Unless otherwise noted, all values for the local skin-friction coefficient C_f used in this paper were obtained from the equations of Hopkins¹⁰ based on the method (II) of Van Driest, into which were put measured or estimated values for M_e , T_r , and R_θ plus the adiabatic wall condition, $T_w/T_r = 1$. Sutherland's formula for viscosity was also used.

Pressure Distributions

An example of a measured pressure distribution is shown in Fig. 4 for the case $\alpha = 25^\circ$. The method of defining the upstream interaction length ℓ_0 illustrated in the figure, is the one used by Settles and Bogdonoff.³

[†]These are empirical fits that we have made to a large body of experimental results obtained by us for an adiabatic, flat-plate boundary layer at $10^5 \leq R_\delta \leq 10^7$ and $1.8 \leq M \leq 5$.

Fig. 4 Definition of interaction length.

Fig. 5 Surface pressure distributions, $M_e = 3.96$, $x_c = 28$ in.

Figure 5 presents a set of pressure distributions obtained at $M_e = 3.96$ for a nominal Reynolds number $R_c = 30 \times 10^6$. (Flares of angle $\alpha > 25^\circ$ were not provided with pressure taps). The listed values of C_{f0} are computed for the point at the beginning of interaction, $x_0 = x_c - \ell_0$, and distances from the corner ξ are normalized with δ_0 , the value for the undisturbed boundary-layer thickness at x_0 . For $\alpha = 40^\circ$ the interaction begins at $\xi/\delta_0 = 25.4$, so only the portion of the pressure distribution near the corner has been plotted in Fig. 5. The nearly constant pressure in this portion is taken to be the plateau pressure, $P_p = 3.12 P_e$. Plateau pressure values obtained at the Mach numbers of this experiment are close to those given for upstream-facing steps by the correlations of Zukoski¹¹ and of Werle¹²; they were found to be insensitive to Reynolds number, as Zukoski had found earlier.

Interaction Length

The complete set of values of the upstream interaction length ℓ_0 obtained over the range of all the parameters is presented in Figs. 6 and 7, in which the interaction lengths have been normalized by x_c and plotted against R_c . While the trends shown in these basic data plots are interesting, a more significant plot would be based on a boundary-layer thickness parameter instead of x_c . When values of ℓ_0/Δ (where $\Delta = \delta, \delta^*$, or θ) are plotted against R_Δ , it is found that ℓ_0/Δ decreases with increasing R_Δ for the whole range of flow parameters, whether Δ be evaluated at x_0 or x_c ; this is similar to the trends found by Settles and Bogdonoff³ and by Law⁴ at $M = 3$ for $\Delta = \delta$. However, these plots are not shown here because a better way to present the data was found, one in which the dependence on Mach number disappears.

For reasons which are not yet understood, when ℓ_0/δ_0 is plotted against C_{f0} , the data for different values of Mach number (excluding the $M_e = 1.98$ data) fall onto a single curve for each value of α , as may be seen in Fig. 8. Values of C_{f0} were determined as previously explained. The data from the present experiments are in the range $10^5 < R_\delta < 10^6$, but in-

Fig. 6 Effect of flare angle and Reynolds number on interaction length: a) $M_e = 1.98$; b) $M_e = 2.49$; c) $M_e = 2.98$; d) $M_e = 3.23, 3.47, 3.73$; e) $M_e = 3.96$; f) $M_e = 4.45$.

cluded on the plots are data in the next higher decade from our previous study,^{1,13} which also fall onto the correlation. It is remarkable that the data for each value of $\alpha < 35^\circ$ (and excluding those for $M_e = 1.98$) fall on a straight line. We denote the slope of the line by σ and the intercept skin-friction value by C_{f0}^* . For $\alpha = 35^\circ$, some liberty has been taken in fitting a straight line to part of the correlation [see remarks following Eq. (5), below]. A discussion of factors contributing to the nonconforming behavior exhibited by the data obtained for $M_e = 1.98$ and for $\alpha > 35^\circ$ is given below. Data for $\alpha = 9^\circ$ and 13° are not included in Figs. 6 and 8 because only a few data points were obtained, and also because of the difficulty (due to orifice spacing) in obtaining precise values of l_0 from surface-pressure measurements for small α . However, four data points obtained for $\alpha = 13^\circ$, $x_c = 28$ in., and $M_e = 2.98$ and 3.96 , when plotted in the format of Fig. 8, were in agreement with a straight line passing through $C_{f0}^* = 0.0008$ with slope $\sigma = 400$.

The straight-line fits may be represented by the equation

$$l_0/\delta_0 = \sigma(C_{f0} - C_{f0}^*) \quad (4)$$

Fig. 7 Interaction length for $\alpha = 40^\circ$.

in which, in addition to the intercept parameter C_{f0}^* (α), there appears the upstream-influence coefficient σ , i.e., the slope of the line, which also depends on α . Values of $\sigma(\alpha)$ are well fitted by the empirical equation

$$\sigma = 10^3 (\alpha/18.29)^{2.81} \quad (5)$$

Fig. 8 Correlation of interaction length with local skin-friction coefficient: a) $\alpha = 19^\circ, 20^\circ, 22^\circ$; b) $\alpha = 25^\circ$; c) $\alpha = 27^\circ, 30^\circ, 35^\circ, 35^\circ, 40^\circ$.

(which was used a posteriori to fit part of the data for $\alpha = 35^\circ$ in Fig. 8). Values of $C_{f0}^*(\alpha)$ are well fitted by the equation

$$C_{f0}^* = 10^{-3} (1 - 0.001189\alpha^2) \quad (6)$$

It is not clear what physical interpretation, if any, to attach to the above curve-fitting equations. The literal implication of Eq. (4) is that, for each α , the upstream interaction length (l_0) becomes zero at a sufficiently high Reynolds number R_δ^* corresponding to C_{f0}^* (the separation length l_s would become zero at somewhat lower Reynolds number). Of course it is not physically realistic for upstream influence to become precisely zero at finite Reynolds number, because a sublayer next to the wall will always be subsonic. A further interesting result is that, according to Eq. (6), C_{f0}^* becomes zero for $\alpha \approx 29^\circ$, implying that for $\alpha > 29^\circ$ there is always an upstream influence (and for somewhat larger α there is always separation) no matter how high the Reynolds number.

Whatever the physical significance of the parameters C_{f0}^* and σ defined in this way, Eq. (4) can be used as an interpolation formula for the interaction length (l_0) as a function of α and C_{f0} . Figure 8 shows one format for displaying

Fig. 9 Upstream influence due to a flare.

Fig. 10 Comparison between present correlation and experimental results of Law⁴.

this dependency; another is given in Fig. 9 for flare angles up to 30° and values of $C_{f0} \leq 0.003$. Higher values of C_{f0} would be in the transition range of Reynolds number for the applicable range of Mach numbers $2.5 \leq M_\infty \leq 5$. In fact, the correlation should be used with caution for $C_{f0} \geq 0.002$, which was the largest value in the present experiments. Over the range of data from which Eq. (4) was derived, there is no effect of the axisymmetric parameter x_c/r (cf. Fig. 8 for $x_c = 14$ and 28 in.) and therefore the correlation is applicable to two-dimensional flow over a ramp.

Law's⁴ experimental results on a two-dimensional (flat-plate/ramp) configuration for $M_\infty \approx 3$ and $10^5 < R_\delta < 10^6$, conditions comparable to that of the present study, are for a broad range of α at 4 discrete values of R_δ . His data are therefore compared in Fig. 10 with the correlation in the form of Fig. 9. The values of C_{f0} were calculated by us as described previously, with the assumption $T_w/T_r = 1$, from data provided by Law.¹⁴ The excellent agreement with part of Law's data and disagreement (up to 20%) with other parts is difficult to reconcile. Apart from quantitative differences, there are curiously abrupt changes (compared to the smooth correlation curves) at about $\alpha = 22^\circ$. This comparison between our data (represented by the correlation) and Law's is not entirely satisfactory.

The recent data of Settles et al.¹⁵ cover a somewhat smaller range of α than Law's but a larger number (22) of R_δ values. It is therefore more practical to compare the data with the correlation in the form of Fig. 8. This is shown in Fig. 11. All data are for $M_\infty \approx 3$ and slightly heated wall conditions (we estimate $T_w/T_r \approx 1.2$ from conditions cited in Ref. 15). A few data were obtained at $10^5 < R_\delta < 10^6$ with an axisymmetric (ogive-cylinder/flare) model for which the axisymmetric parameter was $x_c/r = 14$. The majority of the data were obtained with a two-dimensional (flat-plate/ramp) configuration in a range of Reynolds number, $10^6 < R_\delta < 10^7$, comparable to that of Ref. 1.

Note that in Fig. 11 the experimental data are in terms of conditions at the corner δ_c and C_{fc} , whereas the correlation curves are in terms of δ_0 and C_{f0} . Since the data extend only over the range $0 < l_0/\delta_c < 1.5$, the differences are negligibly small. The notation l_0/δ_c and C_{fc} used in Fig. 11 correspond, respectively, to the notation $\Delta x/\delta_0$ and C_{f0} used in Figs. 15 and 16 and Tables 1 and 2 of Ref. 15. Agreement between the

Fig. 11 Comparison between present correlation and experimental results of Settles et al.¹⁵ at $M_e = 2.90$.

correlation and experiment is good for $10^\circ \leq \alpha \leq 18^\circ$. For $\alpha = 20^\circ$ the agreement is reasonable, considering the variation in the experimental data; the values measured at Sec. 2 and 3 for $\alpha = 20^\circ$ are consistently higher than those obtained at Sec. 1 by about $\Delta(l_0/\delta_c) = 0.15$. We conclude that the experimental data of Ref. 15 tend to confirm our correlation.

Incipient Separation

Incipient separation continues to be a vexing problem. Since its earliest study,² subsequent investigations^{1,3,4,15-18} have continued to produce disagreements. This can be attributed largely to the use of different experimental criteria for defining incipient separation conditions. An excellent review of the situation has been given by Appels¹⁸ who also carried out an investigation of his own at $M = 3.5$ over the range $9 \times 10^4 < R_\delta < 7 \times 10^5$ and at $M = 5.4$ over the range $2 \times 10^5 < R_\delta < 6 \times 10^5$. Appels points out that flow reversal occurs first in the sublayer at small values of α ; the result is a "small separation" region which can be detected, for example by surface-flow techniques, and which grows quite slowly with increasing α , as Spaid and Frisett¹⁶ had noted earlier. At a sufficiently large value of α the outer portions of the boundary layer become involved and the separation length increases with increasing α at a rate that is several times greater than the growth rate observed for the small separation region. These observations led Appels to define two values for α_i at each of his R_δ conditions: the first (low) value of α_i corresponds to the onset of the small separation region, the second (high) value of α_i characterizes the onset of the high growth rate or "large separation" region.

In the present investigation we did not measure α_i . Some rough determinations were made from shock geometry on Schlieren pictures, but we did not consider these to be sufficiently accurate for inclusion here. However, the correlation [Eq. (4)] that has been obtained for upstream influence length can be used for exploring the behavior of α_i . This follows from the observation that the separation point, when it occurs, is always downstream of the beginning of interaction, $\ell_s < \ell_0$. Thus, each straight line in Fig. 8 passes through a value of $\ell_0/\delta_0 > 0$ that corresponds to incipient separation ($\ell_s = 0$). This value of $(\ell_0/\delta_0)_i$ for incipient separation may depend on the parameters of the problem, but an examination of pressure distributions from the present work and Ref. 1 suggests that it may be relatively constant.

To examine this we have plotted the correlation [Eq. (4)] in Fig. 12 with ℓ_0/δ_0 as a parameter—this is the *third* way of presenting the correlation. Also plotted on this figure are experimental values of α_i from various sources^{1,4,15-18} who used either the surface flow ("liquid") technique, the first appearance of a separation shock at the outer edge of the shear layer, or the orifice-dam^{1,8,13} technique to make their deter-

Fig. 12 Experimental values of incipient separation conditions superimposed on the present correlation for upstream influence length.

minations. It is seen that Appels' data from the "small-separation" criterion correspond to $(\ell_0/\delta_0)_i \approx 0.1$, while those from the "large-separation" criterion correspond to $(\ell_0/\delta_0)_i \approx 0.55$. Other data,^{16,17} which correspond to the "small" criterion are in fair agreement with the value $(\ell_0/\delta_0)_i = 0.1$, while those^{1,4,15,16} presumed to correspond with the "large" criterion lie in a band $0.3 < (\ell_0/\delta_0)_i < 0.7$.

In Fig. 12 we have not included values of α_i determined by the appearance of a kink in the surface pressure distribution.^{2,15,16} This is the least sensitive indicator of separation onset; furthermore, there is considerable disagreement among the results of the different investigators using the technique, especially at low Reynolds number; the results from Ref. 16 for incipient separation correspond to values of $(\ell_0/\delta_0)_i$ slightly larger than unity while those from Ref. 2 at similar (low) values of R_δ correspond to values as large as 3. The implication is that boundary-layer profiles were different, perhaps due to differences in recovery from transition or tripping.

This method of presenting the incipient separation data has the effect of compressing a large range of Reynolds number into a small corresponding range of C_f . The effect is dependent upon Mach number and becomes most pronounced as $C_f \rightarrow 0$. With this compression, it is possible to better see the relation of data over a large range of Reynolds number and the effects of data scatter. Viewing the results collectively, we see an independence of M (as in our basic correlation) and a trend for increasing α_i with decreasing C_{f0} (increasing R_δ). An interesting observation is that the limiting value predicted for α_i (at $C_{f0} = 0$) is about 31° ; it would be approached asymptotically as $R_\delta \rightarrow \infty$. In practice, values of $C_{f0} < 0.0006$ can be obtained for adiabatic wall conditions in existing facilities at high (hypersonic) values of Mach number. However, the experimental results available for hypersonic turbulent boundary-layer separation are generally for a cold wall condition ($T_w/T_r < 1$) and so we have not included such data in Fig. 12.

Discussion

Possibly the most remarkable feature of the results presented above is the disappearance of the Mach-number dependence (for $M_e \geq 2.5$) of the interaction length and of the incipient-separation angle when they are plotted against the skin-friction coefficient. Although the correlation was found when looking for possible correlations with law-of-the-wall

parameters, it is not possible to rationalize it in those terms. As previously noted,^{1,19,20} the interaction of a supersonic, turbulent boundary layer with a corner is controlled by a wall interaction layer that is considerably thicker than the sublayer and includes some supersonic portion. Increasing Reynolds number (decreasing C_f) "fills out" the velocity profile and brings the supersonic portion closer to the wall (relative to δ), i.e., it reduces the wall-layer thickness and the related scale of the interaction. It is this effect that controls both the conditions for incipient separation and the interaction length, ℓ_0 . When the external Mach number is too low ($M_e < 2$), the Mach number at the edge of the interaction layer is low enough that the interaction becomes a "transonic" one with rather different characteristics from those at higher Mach numbers. We had noted this in the experiments of Ref. 1. For example, at $M_e = 1.95$, the shock wave ahead of the corner was detached, even for values of α for which the boundary layer had not yet separated. That the present $M_e = 1.98$ data do not fall on the correlation curves in Fig. 8 may be connected with such "transonic" behavior. In passing, we note that the $M_e = 2$ data from Ref. 1 and from the present experiments consistently fall onto values of "effective α " about 4° above those for the correlation curves in Fig. 8.

To obtain a clearer understanding of these interactions requires a rational method for determining the thickness of the postulated wall interaction layer. Our own and other^{19,20} methods for defining it have been ad hoc. Explanations for the Mach-number independence in Fig. 8 and for the linear dependence on C_f await a better understanding of the wall interaction layer.

An important point is that the present correlation is strictly for the adiabatic condition, $T_w = T_r$. It does not apply for $T_w \neq T_r$, even if the effects of heat transfer on C_f are taken into account. For example, the effect of wall cooling ($T_w < T_r$) is to increase C_f ; from the present correlation we might conclude that there is a corresponding increase in ℓ_0/δ_0 but, in fact, a decrease is observed.¹⁶ The explanation is that wall cooling makes the velocity profile fuller and reduces the thickness of the wall interaction layer. In the present experiments, we saw evidence of such wall-temperature effects in Schlieren photographs taken immediately after the tunnel started at the time the total-temperature transient peaked. However, the data reported here and used in the correlations were obtained under stable, nearly constant total-temperature conditions for which the wall temperature was within 5% of the calculated recovery temperature.

With respect to the results for values of α greater than 30° , it may be seen from Fig. 8 that Mach-number independence still exists for $\alpha = 35^\circ$ and 40° , but the data do not fall onto straight-line correlations (as explained earlier, the straight line shown for $\alpha = 35^\circ$ was obtained "after the fact"). It is also noted that these values of α are large enough that the angles through which the separated shear layers must turn at reattachment are approaching the maximum values possible²¹ and even the maximum values possible for turning without shock detachment. Under these conditions, the reattachment point may be expected to move rapidly downstream (with increasing α), and the separation point correspondingly upstream. If the reattachment point reached the shoulder the flow would be basically the same as that ahead of a step, and the separation point would have reached a distance 4.2 step heights upstream of the shoulder.¹¹ In none of the data reported here had this condition yet been reached. Also, for these larger values of α and correspondingly larger separated regions, effect of axial symmetry can be expected, i.e., the separation region should be smaller than in a corresponding two-dimensional flow. This observation is supported by the experience reported in Ref. 21 and the data of Settles et al.¹⁵

In regard to the problem of "incipient separation", the ambiguities that exist among its definitions and measurements are distressing from a strictly scientific point of view. On the

other hand, the ambiguities can be accounted for in most practical cases by adopting either the "large" or "small" separation region criterion, as conditions warrant. Nevertheless, the need still exists for further clarification of the definition and its corresponding dependence upon the parameters of the problem. The last word on this problem has not yet been written.
